Summary

This study was designed to find the correlation between changes in CD⁴⁺ cell count, lipid profile and liver marker enzymes in HIV-infected and AIDS patients. The study population consisted of 150 subjects, age and sex-matched and divided into three groups [control subjects (n=50), HIV infected (n=50) and AIDS patients (n=50)]. We observed a significant reduction in CD⁴⁺ cell count in HIV/AIDS patients when compared to control subjects. Serum levels of total cholesterol, high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C) were found to be decreased significantly in HIV/AIDS patients when compared with normal counterparts. On the other hand, the levels of triglyceride (TG) and very low-density lipoprotein cholesterol (VLDL-C) were markedly elevated in HIV/AIDS patients compared to normal subjects. The activities of serum aspartate aminotransferase (AST), alanine aminotransferase (ALT) and alkaline phosphatase (ALP) observed in HIV/AIDS patients were significantly higher than in the control group. Further, the above mentioned haematological and biochemical variables were found to be affected more significantly in AIDS patients when compared with HIV infected subjects. Hence, it may be concluded that CD⁴⁺ cell count, lipid profile and liver enzymes can be a good index of disease progression in HIV infection and AIDS patients.

Key words: HIV – AIDS – CD⁴⁺ cell count – lipids – liver enzymes

INTRODUCTION

The acquired immunodeficiency syndrome (AIDS), is a fatal illness caused by a retrovirus known as the human immunodeficiency virus that breaks down the body's immune system, infects CD⁴⁺ cells initially and progressively leads to AIDS (Rasool et al. 2008). There are 2.47 million persons in India living with HIV; equivalent to approximately 0.36% of the adult population. The revised national estimate reflects the availability of improved data rather than a substantial decrease in actual HIV

prevalence in India. The transmission route is still predominantly sexual (87.4%); other routes of transmission by order of proportion include prenatal (4.7%), unsafe blood and blood products (1.7%), infected needles and syringes (1.8%) and unspecified routes of transmission (4.1%) (UNAIDS 2006).

Initial cases of advanced immune deficiency (almost immediately associated with CD4 T-lymphocyte depletion) often with striking opportunistic infections or malignancies, led to the recognition of the AIDS epidemic. Tests for HIV-induced antibodies found a large epidemic, mostly of those not yet ill but with signs of progressive immune depletion. Clinical attention thus appropriately shifted from AIDS to HIV and the recognition that HIV infection is a disease in its own right requiring appropriate treatment (Volberding 1989). HIV infects CD4⁺ cells and can be directly cytotoxic. Other complex mechanisms however, appear important in explaining the progressive depletion of this key cellular element of immunity (Jaworowski et al. 1999, Hazeberg et al. 2000). Immune-mediated cytotoxicity is probably involved, as T-cell regeneration in the thymus is also limited by HIV infection (McCune et al. 2000, Smith et al. 2000). Along with CD4 T cells, macrophages/monocytes are also infected. These cells might have a key role in maintaining and spreading HIV within the body and are probably not directly killed by infection. Along with CD4⁺ cell depletion, infection damages many components of normal immunity. T-cell proliferative response, especially to HIV antigens, is quickly lost and the repertoire of antigen recognition diminishes with time.

Men with HIV infection were reported to have hypocholesterolaemia with and without hypertriglyceridaemia (Grunfeld et al. 1991, National AIDS Control Organization - NACO 2003, Anastos et al. 2007). An association between plasma triglyceride and circulating interferon-levels has been observed in persons with AIDS. However, the mechanism for hypocholesterolaemia in HIV and other infections is not known. A pattern of hyperlipidaemia (i.e. elevated levels of total cholesterol, low-density lipoprotein cholesterol, and triglycerides, and a reduced level of high-density lipoprotein cholesterol) has been observed in patients treated with protease inhibitors (Crook and Mir 1999, Ducobu and Payen 2000, Khiangte et al. 2007). Infection can increase plasma triglyceride levels by decreasing the clearance of circulating lipoproteins, a process considered to be the result of reduced

lipoprotein lipase (LPL) or by stimulating hepatic lipid synthesis through increases in either hepatic fatty acid synthesis or re-esterification of fatty acid derived from lipolysis (Grunfeld et al. 1992). Hypertriglyceridaemia was the first dyslipidaemia to be reported in HIV infected patients, but other lipid abnormalities such as hypocholesterolaemia or hypo HDL cholesterolaemia have also been reported.

The CD4⁺ lymphocyte is the primary target of HIV infection because of the affinity of the virus to the CD4⁺ surface marker. Infection with HIV leads to a progressive impairment of cellular functions, characterized by a gradual decline in peripheral blood CD4⁺ lymphocyte levels which results in an increasing susceptibility to a wide variety of opportunistic, viral, bacterial, protozoal, and fungal infections and to certain malignancies also (Khiangte et al. 2007). Thus HIV can make copies of its own genome as DNA in the host's cells such as human T4-helper lymphocytes and this leads to the elaboration of vast numbers of viral particles (Montagnier et al. 1984). Although immunological dysfunction is common to all AIDS patients, the clinical spectrum of HIV infection is diverse and multiple organ involvement is frequently evident (Dalglish et al. 1984). Liver disease has been linked to HIV infection and may manifest as fever of unknown origin, hepatomegaly or sub-clinical abnormalities in liver function tests (Tietz et al. 1983, Montagnier et al. 1984). Studies also suggested that the major cause of hepatitis in HIV patients is infection by a secondary virus called the cytomegalo virus. It is also of interest that HIV has been detected in the liver cells of AIDS patients. It may be that those cells targeted for apoptosis are the same cells infected with HIV (Cooper et al. 1984).

In various forms of liver disease, serum levels of numerous cytosolic, mitochondria and membrane-associated enzymes are increased. The degree of elevation varies with the type of disease. Alanine and aspartate aminotransferases and alkaline phosphatase are the enzymes that are most often measured for evaluation of liver disease or diseases affecting the liver or in diseases where the liver is implicated (Tietz et al. 1983). The knowledge of the intracellular location of enzymes can therefore assist in determination of the nature and severity of a pathological process if suitable enzymes are assayed in the blood. The present study was undertaken to find out the relationship between changes in CD4⁺ cell count, lipid profile and liver marker enzymes in HIV infection and AIDS patients.

MATERIALS AND METHODS

Study population

The population was selected consisting of 150 subjects divided into three groups: HIV infected patients 50 cases (n=50), AIDS patients 50 cases (n=50) and an equal number of age- and sex-matched control subjects (n=50). The study was carried out at the K.G. Hospital and Post Graduate Medical Institute, Coimbatore, Tamil Nadu, India from January 2006 to January 2008. For diagnosis and confirmation of HIV infection, we followed the National AIDS Control Organization (NACO) recommendations for HIV testing (NACO 2003). All the patients were subjected to detailed history taking and clinical examination. The informed consent of the patients was obtained before testing.

Biochemical investigation

Red blood cell count, total white blood cell count, platelet count, total hemoglobin, hematocrit and ESR were determined using a fully automated hematology analyzer (Pentra-XL 80, Horiba ABX, USA). Fasting blood glucose, serum total cholesterol, triglyceride, HDL, LDL and serum enzymes (AST, ALT and ALP) were estimated by a fully automated clinical chemistry analyzer (Hitachi 912, Boehringer Mannheim, Germany). VLDL cholesterol was calculated by the Friedewald equation. The CD⁴⁺ lymphocyte count was estimated by Fluorescence Activated Cell Sorter (FACS) count system (Becton Dickinson, USA).

Statistical analysis

All data were expressed as mean $\pm$ SD. The statistical significance was evaluated by student 't' test (two-tailed). A p value of <0.05 was considered statistically significant. Statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS Cary, NC, USA) version 10.0.

RESULTS

Information about the investigated characteristics is shown in Table 1. The mean age limit was 36 ± 9 in AIDS patients, 32 ± 5 in HIV infected patients and 30 ± 6 in control subjects. The decreased body mass index in AIDS patients (25 ± 5.3 kg/m²) compared with HIV infected patients (29 ± 6.2 kg/m²) and control subjects (34 ± 6.2 kg/m²) were

statistically significant. There was an increased number of hypertension sufferers and smokers observed in AIDS patients compared with HIV infection and control subjects. Diabetic participants were defined as those with a fasting blood glucose concentration >120 mg/dl.

Table 2 shows the levels of CD⁴⁺ cell count, total RBC count, WBC count, platelet count, hemoglobin, hematocrit and ESR in control, HIV infected and AIDS patients. The levels of CD⁴⁺ cell count, total RBC count, platelet, hemoglobin and hematocrit were significantly decreased in AIDS patients when compared with HIV infected patients and control subjects. On the other hand, the level of total WBC count and ESR were significantly increased in HIV infected and AIDS patients. The above mentioned haematological parameters were found to be more significantly altered in AIDS patients compared with HIV infected subjects.

The plasma concentrations of lipids (total cholesterol, triglyceride, HDL, LDL and VLDL) and serum enzymes (AST, ALT and ALP) in control and HIV infected and AIDS patients are depicted in Table 3. The levels of total cholesterol, HDL and LDL were significantly decreased, while the level of triglyceride and VLDL were significantly increased in AIDS patients when compared to HIV infected patients and normal subjects, but the levels of VLDL in the HIV infected patients and control subjects did not differ significantly. The activities of serum liver marker enzymes observed in AIDS patients significantly increased in the HIV infection patients and control subjects. The above biochemical variables were found to be altered more significantly in AIDS patients when compare with HIV infected subjects.

DISCUSSION

The present study showed that the lipid profile was altered in HIV infected and AIDS patients. Alteration in the lipid profile occurred even during the early stages of HIV infection and more so as the disease progressed. Of the total 50 cases, 46 (92%) were classified as having AIDS according to Clinical Case Definition of AIDS. This high number of AIDS cases and the fact that there were no patients in the clinical stage in our study could be due to the fact that patients with HIV infection seek hospital admission only in the late clinical stages when they have opportunistic infections (NACO 2003).

Previous studies have demonstrated that patients

with AIDS exhibit highly abnormal total lipid concentrations in plasma (Mullamitha and Pazare 1999). A few authors have determined the levels of plasma triglycerides, total cholesterol and HDL cholesterol in HIV infected individuals by the level of immunological deficiency according to the CD⁴⁺ cell count, and they also came to the same conclusion: with an increase of immunological deficiency and clinical development of HIV infection, lipid profile disorders – indicated by an increase in triglyceride level and decreased

concentrations of HDL cholesterol – also intensified (Rogowska-Szadkowska and Borzuchowska 1999, Ducobu and Payen 2000). Consistent with earlier reports, our study also showed similar findings in which the decrease of CD⁴⁺ count due to disease progression was accompanied by a decrease in total cholesterol, HDL and LDL, and an increase in triglyceride and VLDL levels.

Our findings are also consistent with reports from Ducobu and Payen (2000), who stated that

ALT (IU/l)	17 ± 9.6	73 ± 13.2 ^{xx}	175 ± 22.6 ^{**x}
ALP (IU/l)	75 ± 22.8	180 ± 20.4 ^{xx}	216 ± 28.6 ^{**x}

Symbols as in Table 1

HIV infection induced an early decrease of cholesterol and a late increase of triglyceride with a reduction of HDL. These changes were proportional to the lowering of the CD⁴⁺ count, which reflected the severity of infections, as was the case in our study. However, some authors (Crook and Mir 1999, Ducobu and Payen 2000) reported that patients with AIDS had increased levels of LDL cholesterol, which contradicted our findings. Shor Posner et al. (1995) reported similar findings in which they showed significantly low levels of total cholesterol, HDL and LDL in HIV infected patients, and about 40% of the HIV-infected subjects were demonstrated hypocholesterolaemic when compared to seronegative controls. This low level of total cholesterol, HDL and LDL was reported to be associated with elevated levels of β -2 microglobulin. Low cholesterol levels are prevalent even during the early stages of HIV and associated with a specific alteration in immune function. Kereveur et al. (1996) stated that hypocholesterolaemia observed in the early and hypertriglyceridaemia in the later stage of the infection are due to cytokine effects on different enzymes of lipid metabolism.

Grunfeld et al. (1991) has reported that HIV/AIDS is characterized by a high prevalence of hypertriglyceridaemia and hypocholesterolaemia,

and also an elevated level of cytokines. They observed that decreased cholesterol and cholesterol containing lipoproteins in both AIDS and HIV infection precede the appearance of hypertriglyceridaemia. Increased TG levels in AIDS were primarily due to an increase in VLDL. They also raised the possibility that with the development of AIDS, subsequent increase in IFN may have contributed to an increase in plasma triglyceride levels by decreasing the clearance of TG. The increase of triglyceride catabolism in relation to a reduction of lipoprotein lipase activity was responsible for these lipid changes. Many cytokines such as IFN, IL and TNF probably play a pathogenic role in the dyslipidaemia of HIV (Rogowska-Szadkowska and Borzuchowska 1999). Hence, it may be suggested that the lipid profile can be a good index of disease progression in HIV infection and AIDS patients.

Haematological abnormalities are among the most common complications of infection with HIV (Coyle 1997). Depending on the study setting, anaemia can be found in 63–95% of those with HIV infection at some point during the course of their disease (Sullivan et al. 1998). Chronic thrombocytopenia develops in approximately one third of individuals infected with the human immunodeficiency virus during the course of the

acquired immunodeficiency syndrome (Walsh et al. 1984, Karparkin 1987, Harbol et al. 1994).

In this study, we noticed a significant increase in serum liver marker enzymes (ALT, AST and ALP) in HIV/AIDS patients compared with the control group. Our results are also consistent with the earlier findings of Wildup et al. (1993) who recorded a significant increase in the activities of the three afore-mentioned enzymes investigated. It is of interest to note that HIV has been detected in the liver cells with noticeable pathogenesis of the affected cells in infected individuals and since HIV infection and AIDS patients tend to suffer more chronic, unrelenting forms of many secondary diseases, it is therefore likely that the liver too will be affected and that subsequently changes will occur in the activities of the liver enzymes in HIV infection and AIDS patients. HIV attack host cells and take over the control of the infected cells leading to eventual death of the cells and subsequently the release of cellular contents into the surrounding medium of which enzymes constitute 20%. This may be responsible for the increase in the level of liver enzymes in infected liver cells. Changes in the three mentioned liver enzymes should not be surprising since it is likely that an intact immune response to viral replications is necessary to produce the hepatocellular necrosis and inflammation seen in active hepatitis due to HIV infection and AIDS.

Other causes of increased serum enzymes include: hepatitis due to hepatitis B virus, HCV, drug toxicity, extra-hepatic cholestasis, cirrhosis, hepatobiliary disease, genetic abnormalities with increased production of enzymes, enzyme induction and proliferation of enzyme producing cells, for example, in cancer patients, but these conditions were not exhibited in the patients examined. It is possible nonetheless, that these other conditions could be secondary to HIV infection and thus contribute to an increase in the activities of the liver enzymes examined perhaps to different degrees (Oguntibeju and Banjoko 2003). A detailed analysis, which could include differential enzyme studies, could clarify other sources of ALT, AST and ALP increase in serum. From these findings it therefore becomes necessary to estimate serum levels of ALT, AST and ALP, other liver enzymes and isoenzymes in HIV and AIDS patients to be able to at least monitor prognosis and progressive involvement of the liver cells. This would require continuous monitoring of the patient. In such a case, a sharp increase from the steady state concentrations in a particular patient may be an indication of early or late involvement of the liver

cells either mildly or severely in the absence of other known causes. It is likely that the changes in haematological and biochemical parameters induced by HIV infection will have biological and possibly pathological importance in the development of AIDS and related complications. It is also recommended that the results obtained in this study be used as baseline in the pre-intervention and subsequent management of HIV infection and AIDS patients.
